ABSTRACT

We present 3rd interplanetary network (IPN) localization data for 56 gamma-ray bursts in the GRANAT/ WATCH catalog which occurred between 1990 November and 1994 September. These localizations are obtained by triangulation using various combinations of spacecraft in the IPN, which consisted of *Ulysses* , BATSE, *Pioneer Venus Orbiter* (PVO), *Mars Observer* (MO), WATCH, and PHEBUS. The intersections of the triangulation annuli with the WATCH error circles produce error boxes with areas as small as 16 sq. arcmin., reducing the sizes of the error circles by up to a factor of 800.

Subject headings: catalogs – gamma rays: bursts

1. Introduction

The multi-wavelength counterparts to numerous gamma-ray bursts (GRBs) have now been identified using the rapid, precise localizations available from the BeppoSAX spacecraft (e.g. Costa et al. 1997; van Paradijs et al. 1997), as well as from the *Rossi X-Ray Timing Explorer* and the IPN. However, there is still a need for less precise GRB localizations of older bursts, for several reasons. For example, the discovery of bright optical emission coincident with one burst (Akerlof et al. 1999) indicates that searches through archival optical data may reveal other examples of this interesting phenomenon. Also, the possible association of one GRB with a nearby supernova (Galama et al. 1998), if valid, means that other such associations may exist in the historical records. Because the current rate of rapid, precise localizations remains low ($\sim$ 8 events/year), it is important to add as many bursts as possible to the existing database. The GRANAT/WATCH GRB catalog contains data on 95 bursts observed between 1989 and 1994 (Sazonov et al. 1998); of the 95, 47 bursts were localized to error circles with radii between 0.2 and 1.6 °. The 3rd interplanetary network (IPN) began operations in 1990 with the launch of the *Ulysses* spacecraft. By combining WATCH data with IPN data, it is possible to reduce the sizes of these error circles by as much as a factor of 800, making them more useful for archival studies. This is the 7th in a series of catalogs of IPN localizations. The supplements to the BATSE 3B and 4Br catalogs appeared in Hurley et al. (1999a,b; 218 and 147 bursts, respectively). Localizations involving the *Mars Observer* (MO) and *Pioneer Venus Orbiter* (PVO) spacecraft have been presented in Laros et al. (1997, 1998; 9 and 37 bursts, respectively). Fifteen *Ulysses* , PVO, SIGMA, WATCH, and PHEBUS burst localizations were published in Hurley et al. (2000a). *Ulysses* /BeppoSAX bursts may be found in Hurley et al. (2000b; 16 bursts). Localization data for the bursts in all these catalogs may also be found on the IPN website [2].

2. Instrumentation

The gamma-ray bursts in this paper were observed by at least two instruments. One was the omnidirectional GRB detector aboard the *Ulysses* spacecraft, consisting of two 3 mm thick hemispherical CsI scintillators with a projected area of $\sim$ 20 cm^2 in any direction. The instrument observes bursts in the 25 - 150 keV energy range in either a triggered mode, in which the time resolution is as high as 8 ms, or, for the weaker bursts, in a real-time mode, in which the time resolution is between 0.25 and 2 s. A more complete description of the experiment may be found in Hurley et al. (1992).

The second was the WATCH experiment aboard the GRANAT spacecraft. WATCH employs a unique rotating modulation collimator technique to determine the positions of bursts to $\sim 1\,^{\circ}$ accuracy. The detector is a scintillator operating in the 8 - 60 keV range with a field of view of 74 $^{\circ}$ and a maximum effective area of 47 cm^2. Four independent modules were deployed aboard the GRANAT spacecraft, and $\sim$80% of the sky was monitored with them. See Sazonov et al. (1998) for a more detailed description.

To localize the GRBs in this supplement, use was sometimes made of the data from other experiments, too. These are noted in the following section.

3. Technique

The methodology employed here is similar or identical to that used for the *Ulysses* supplement to the BATSE 3B and 4B catalogs (Hurley et al. 1999a,b). Each WATCH

---

[2]ssl.berkeley.edu/ipn3/index.html

burst was searched for in the *Ulysses* data. One or more annuli of possible arrival directions was derived by triangulation for each burst identified using the data from *Ulysses* and at least one other instrument. The bursts in this catalog thus fall into one of the following categories.

1. Event observed by *Ulysses* and WATCH only. In this case, the triangulation annulus was obtained utilizing the data of these two instruments.

2. Event observed by *Ulysses* , WATCH, and PHEBUS. PHEBUS was also aboard the GRANAT spacecraft (Barat et al. 1988; Terekhov et al. 1991). It consisted of six 12 cm. long by 7.8 cm. diameter BGO detectors oriented along the axes of a Cartesian coordinate system, operating in the 100 keV - 100 MeV energy range, with 1/128 s to 1/32 s time resolution. In this case, the triangulation was done using *Ulysses* and the instrument which resulted in the most precise triangulation annulus. The WATCH data have the advantage of being taken in an energy range which corresponds more closely to that of *Ulysses* , but the time resolution of the WATCH data was sometimes rather coarse ($\sim$ 10 s or more). On the other hand, the PHEBUS data, although taken in an energy range higher than that of *Ulysses* , have the advantages of good time resolution and in some cases better statistics. The more accurate of the two possible triangulation annuli is quoted here.

3. Event observed by *Ulysses* , WATCH, and BATSE. BATSE consists of eight detector modules aboard the *Compton Gamma-Ray Observatory* (GRO). Each module has an area $\sim$ 2025 cm^2. The DISCSC data type was used, which gives 0.064 ms resolution data for the 25-100 keV energy range. BATSE is described in Meegan et al. (1996). For the purposes of triangulation, the GRANAT and GRO spacecraft were close enough to one another ($<$

250 light-ms) that the accuracy of the triangulation could not be improved by including the data from both spacecraft. (For comparison, the *Ulysses* -Earth distance was as great as several thousand light-seconds.) In this case, the *Ulysses* - BATSE annulus was used, since the BATSE energy range corresponds closely to that of *Ulysses* , the time resolution is good, and the statistics are always better. These annuli have appeared in Hurley et al. (1999a), but their intersections with the WATCH error circles are presented here for the first time. The BATSE error circles may be found in Meegan et al. (1996). In those cases where WATCH did not localize the burst, the *Ulysses* - BATSE localization information consists of the intersection of the IPN annulus with BATSE error circle. Because the error circle is large, the curvature of the annulus does not allow a simple description of error box, and no localization information appears in table 2; it may be found in Hurley et al. (1999a).

4. Event observed by *Ulysses* , WATCH, and one or more of the following experiments: BATSE, COMPTEL (Kippen et al. 1998), SIGMA (Claret et al. 1994), PVO (Laros et al. 1997), or MO (Laros et al. 1998). Here, triangulation using PVO or MO data, and/or the independent localization capabilities of COMPTEL or SIGMA, have been utilized. These special cases are noted in table 2, and the previously published error box coordinates have been included in the table for convenience. In most cases the error box is fully contained within the WATCH error circle. If no figure has been previously published showing the WATCH error circle and the IPN triangulation result, one appears in this paper.

4. The data

In table 1 the WATCH bursts also detected by *Ulysses* are listed. Column 1 gives the date, column 2 gives the detection time at WATCH, and column 3 indicates the *Ulysses* data mode (RI for rate increase, observed in the low time resolution real-time mode, trigger for the high time resolution triggered mode). Column 4 indicates whether BATSE observed the burst. Here N/O means not observable (GRO had not been launched yet), and a number, if present, is the BATSE trigger number. Column 5 indicates whether the burst was localized by WATCH, and column 6 indicates whether PHEBUS observed the event.

Table 2 gives the localization information for the events in table 1. Columns 1 and 2 give the date and the time. For those bursts localized by WATCH, columns 3 and 4 give the right ascension and declination of the center of the WATCH error circle (J2000), and column 5 gives the WATCH 3 σ error circle radius. These data are taken directly from Sazonov et al. (1998). Columns 6 and 7 give the right ascension and declination α, δ of the center of the IPN annulus (J2000); columns 8 and 9 give the radius R of the center line of the annulus, and the 3 σ half-width of the annulus δR. That is, the annulus is described by two small circles on the celestial sphere both centered at α, δ, with radii R-δR and R+δR. For those cases where there is a WATCH error circle and the annulus intersects it, additional data are given in columns 10 and 11. (The possible exceptions are first, cases where the IPN annulus is wider than the error circle diameter and therefore does not intersect it, and second, cases where an actual error box has been obtained and published elsewhere.) Column 10 gives the right ascensions and declinations (J2000) of the IPN error box and column 11 gives the error box area. Note that, strictly speaking, it is not possible to define a true error box with straight line segments between the four intersection points of a WATCH error circle with an IPN annulus due to the curvatures of both the annulus and the error circle. However, for many purposes, this may be negligible.

5. Discussion and Conclusions

There is good agreement between the IPN annuli and the WATCH error circles in all cases. We call attention to some of the more precise error boxes:

1. 940703. The error box area is 16 sq. arcmin., a reduction in area from the 0.24° WATCH error circle of a factor of ∼41.

2. 921022. The error box area is 22 sq. arcmin., a reduction in area from the 0.72° WATCH error circle of a factor of ∼265.

3. 921013. The error box area is 32 sq. arcmin., a reduction in area from the 1.51° WATCH error circle of a factor of ∼800.

The localizations in table 2 are presented in figures 1-25. (Figures for the WATCH bursts involving SIGMA, which have already appeared in Hurley et al. (2000a), have been omitted.) As these figures show, the combination of WATCH and the IPN results in very precise location information for these bursts. Another version of the WATCH experiment was flown aboard the EURECA spacecraft. Analysis of these events is currently underway.

KH is grateful to JPL for *Ulysses* support under Contract 958056, and to NASA for Compton Gamma-Ray Observatory support under grant NAG 5-3811.
